A Two-level Auction for C-RAN Resource Allocation

Mira Morcos*, Tijani Chahed†, Lin Chen‡, Jocelyne Elias§ and Fabio Martignon‡

Abstract—In this paper we propose and evaluate an auction-based resource allocation mechanism in a Cloud-based Radio Access Network (C-RAN), where the spectrum is managed by several Mobile Virtual Network Operators (MVNOs) and the physical resource is owned by the C-RAN operator. Technically, our approach consists of two coupled auctions in a hierarchical way: the lower-level auction between end users and the virtual operators and the higher-level one between MVNOs and the C-RAN operator. The proposed auction-based approach satisfies fundamental economic properties such as truthfulness. We also numerically analyze the auction results in several typical network settings, considering both homogeneous and heterogeneous resource demands.

Index terms—Resource Allocation, C-RAN, MVNO, Auction.

I. INTRODUCTION

Next generation (5G) mobile networks are promising 25 times the data rate provided by the current generation [1], higher efficiency, enhanced mobility support and seamless management of connected devices. In order to provide such features, and more importantly, a better efficiency in resource utilization as well as reduced CAPEX and OPEX, the Cloud-RAN (or Virtual RAN) paradigm has been recently proposed. Indeed, C-RAN shares with cloud computing functionalities like centralization to facilitate resource management and virtualization to reduce physical resources’ costs and maintenance [2]. In this paper, we focus on resource management by proposing an auction-based resource allocation mechanism in a Cloud-based Radio Access Network (C-RAN), where the spectrum is managed by several virtual mobile operators (MVNOs) and the physical resource is owned by the C-RAN operator.

Our approach consists of two coupled auctions in a hierarchical way: the lower-level auction between end users and the virtual operators, and the higher-level one between MVNOs and the C-RAN operator. Our motivation of using auction-based resource allocation is both economical and technical. Economically, auctions are well-adapted in markets to maximize the revenue of sellers (or auctioneers). Technically, auctions can increase the efficiency of the resource utilization. We demonstrate that our designed auction mechanism satisfies crucial economic properties, in particular truthfulness (players' dominant strategy is to reveal/bid their true valuations) and is computationally efficient. Finally, we perform an extensive numerical analysis, implementing our proposed approach in several, typical mobile network scenarios, measuring the utility (payoff) obtained by all players’ involved in the resource allocation process. We show in this way the effectiveness of our scheme in terms of efficient resource allocation, considering both homogeneous and heterogeneous user demands.

Recently, auction theory has been extensively applied in resource allocation in computing and communication systems to increase the system efficiency, but few consider the case of two hierarchical, coupled auctions as in our setting. The work in [3] describes and proposes different auction approaches that can be applied to radio resource allocation (like spectrum and power allocation). The authors in [4] introduce an auction design between a MVNO and the radio service provider that aims to maximize the social welfare for an efficient and fair allocation. The work also suggests a greedy algorithm to reduce the time complexity of the proposed solution. In [5], a 2-level hierarchical combinatorial auction is proposed for 5G networks between the infrastructure provider, MVNO and User Equipments (UEs); two models are stated: a single seller-multiple buyer model and a multiple buyers-multiple sellers model. A backward induction method is proposed to solve the winner and price determination problems. In [6] and [7], the Myerson concept of virtual valuation is used to design a truthful auction for spectrum allocation.

This paper is organized as follows. Section II presents the system model, as well as the assumptions we considered in our work. Then, in Section III we formulate our proposed auction-based architecture, and we prove in the following sections key properties ensured by our scheme. Numerical results are illustrated and discussed in Section VI. Finally, Section VII concludes the paper and discusses future research issues.

II. SYSTEM MODEL AND TWO-LEVEL AUCTION

In this section, we first present the system model we consider in our work; then we formulate the two coupled auctions we designed to efficiently allocate network resources in such scenario.

More specifically, we consider a C-RAN where the physical spectrum resource is owned by the C-RAN operator who sells the spectrum to \( m \) virtual mobile operators (MVNOs, indexed from 1 to \( m \)), where \( MVNO_j \) serves \( N \) subscribed users, as shown in Figure 1. There are \( Q \) resource blocks owned by
the C-RAN operator, which are shared among the MVNOs. In our work, we consider the most competitive case where any resource block cannot be used by two users simultaneously.

A. The two-level auction

We develop a two-level auction-based resource allocation scheme, as shown in Figure 2: the higher-level auction runs between the C-RAN operator and the MVNOs; the lower-level auction between each MVNO and the end users it serves.

More specifically, the agents of the auction are:

- The C-RAN operator: Also referred to as Cloud, it is the auctioneer at the higher-level auction that initiates the auction over Q resource blocks.
- MVNOs: Each MVNO \( j \) (1 ≤ \( j \) ≤ \( m \)) has two roles: a bidder in the higher-level auction and an auctioneer in the lower-level auction.
- End users: End users are bidders in the lower-level auction. They bid for the resource blocks to satisfy their service need. Specifically, the users served by MVNO \( j \) participate to the lower-level auction of this same MVNO.

The commodities of the auctions are the resource blocks. The bids are signals that inform the auctioneer about the bidder demands in terms of resource blocks and the offered price they are willing to pay in order to purchase the commodities.

More in detail, our auction proceeds as below with the notations reported in Table I:

<table>
<thead>
<tr>
<th>Term</th>
<th>Interpretation</th>
</tr>
</thead>
<tbody>
<tr>
<td>MVNO(_j)</td>
<td>( j )-th MVNO from a total of ( m ) participating in ( \text{Auction}_1 )</td>
</tr>
<tr>
<td>UE(_{i,j})</td>
<td>MVNO(_j) ( i )-th user, from a total of ( N ) users, participating in ( \text{Auction}_j )</td>
</tr>
<tr>
<td>( B_j )</td>
<td>MVNO(_j)'s bid, where ( S_j = P_j ) is the weight and the price to be paid</td>
</tr>
<tr>
<td>( b_{i,j} )</td>
<td>UEs bid vector, where ( d_{i,j} ) is the demand and ( w_{i,j} ) the corresponding offered price</td>
</tr>
<tr>
<td>( R_j )</td>
<td>Number of resources allocated to MVNO ( j )</td>
</tr>
<tr>
<td>( U_j )</td>
<td>MVNO ( j ) utility functions</td>
</tr>
<tr>
<td>( p_j )</td>
<td>Winners and price vectors of MVNO ( j )’s end users.</td>
</tr>
</tbody>
</table>

1) In the first step, each user associated to MVNO \( j \), denoted as UEs, submits a bid vector \( \langle b_{i,j} \rangle \) to MVNO \( j \), where:
   - \( d_{i,j} \) is an integer indicating the number of resource blocks required by UEs.
   - \( w_{i,j} \) is the price that user UEs is willing to pay to purchase \( d_{i,j} \). \( w_{i,j} \) is always less than or equal to \( v_{i,j} \), the true valuation of UEs for receiving \( d_{i,j} \). \( v_{i,j} \) is a private information, only known by the user itself.
   We define \( b_j = \langle b_{1,j},...,b_{N,j} \rangle \), MVNO \( j \) users bids set.

2) In the second step, each MVNO \( j \) submits a bid vector \( S_j \) based on the bids received in the lower-level auction, i.e., \( b_j \). We define the \( m \)-dimension bid vector \( S = \langle S_1,...,S_m \rangle \).
   Based on \( S \), the C-RAN operator allocates to MVNO \( j \) resource blocks and charges him \( P_j = S_j \). We denote by \( R = \langle R_1,...,R_m \rangle \) the allocation set to the \( m \) MVNOs participating in \( \text{Auction}_1 \).

3) In the third step, each MVNO \( j \) according to \( R_j \) determines the winner vector \( x_j = \langle x_{1,j},...,x_{N,j} \rangle \), where
   \[
   x_{i,j} = \begin{cases} 
   1 & \text{if } UEs \text{ wins the auction} \\
   0 & \text{otherwise}
   \end{cases}
   \]
   The allocation vector \( a_j \) is defined as
   \[
   UEs : b_{i,j} = \langle d_{i,j}, w_{i,j} \rangle \quad \Rightarrow \quad a_{i,j} = \langle d_{i,j}, p_{i,j} \rangle
   \]
   where
   \[
   a_{i,j} = \begin{cases} 
   \langle d_{i,j}, p_{i,j} \rangle & \text{if } UEs \text{ wins the auction} \\
   (0,0) & \text{otherwise}
   \end{cases}
   \]
   The utility functions of the players in the auction are calculated as follows:
   - UEs’ utility:
     \[
     u_{i,j} = v_{i,j} - p_{i,j}
     \]
• MVNO_j’s utility:

\[ U_j = \sum_{i=1}^{N} p_{i,j} - P_j \]  

(2)

• the C-RAN operator’s revenue:

\[ R_{C-RAN} = \sum_{j=1}^{m} P_j. \]  

(3)

III. RESOURCE ALLOCATION, WINNER AND PRICE DETERMINATION

We now illustrate how resources are allocated in both auctions, as well as the winners’ determination and the corresponding price each player has to pay.

A. Higher-level auction

In the higher-level auction, the C-RAN operator allocates \( R_j \) resource blocks to MVNO_j as follows

\[ R_j = \frac{S_j Q}{\sum_{i=1}^{m} S_i + S_0}, \]  

where \( S_0 \) is a reserved bid set by the cloud to avoid low bids.

The utility of MVNO_j is

\[ U_j = \sum_{i=1}^{N} p_{i,j} - S_j. \]  

(5)

Each MVNO_j needs to calculate the optimal \( S_j^* \) in order to maximize his profit \( U_j \).

B. Lower-level auction

In the lower-level auction, we first derive the optimal strategy for each MVNO. Due to its complexity, we further propose a greedy strategy.

1) Optimal solution: In auction_j, we adopt the sealed bid VCG auction where the user either wins all he asked for or nothing, and then pays the harm it causes to the other players [8]. We denote by \( p_{i,j}^{VCG} \) the VCG price that \( UE_{i,j} \) pays:

\[ p_{i,j}^{VCG} = \max_{b_{-i,j}} \sum_{k \neq i}^{N} p_{k,j} x_{k,j} - \max_{b_{-i,j}} \sum_{k \neq i}^{N} p_{k,j} x_{k,j} \]  

(6)

where \( b_j \) denotes the set of all MVNO_j’s users bid vectors, while \( b_{-i,j} \) indicates the set of all MVNO_j’s users bid vectors except for \( UE_{i,j} \)’s bid: \( b_j = (b_{ij}, b_{-i,j}) \). Knowing his allocation part, \( R_j \), obtained from auction_j, MVNO_j determines the winners by maximizing his profit:

\[ \max_{i=1}^{N} \sum_{i=1}^{N} p_{i,j} x_{i,j} \]  

s.t. \[ \sum_{i=1}^{N} r_{i,j}^{k} = d_{i,j} x_{i,j} \]  

(8)

\[ \sum_{i=1}^{N} r_{i,j}^{k} \leq 1 \]  

(9)

where

\[ x_{i,j} = \begin{cases} 1 & \text{if } UE_{i,j} \text{ wins the auction} \\ 0 & \text{otherwise} \end{cases} \]  

\[ p_{i,j} = \begin{cases} p_{i,j}^{VCG} & \text{if } UE_{i,j} \text{ wins the auction} \\ 0 & \text{otherwise} \end{cases} \]  

We denote by \( r_{i,j}^{k} \) the k-th resource block MVNO_j owns and allocates to \( UE_{i,j} \), such that \( 1 \leq k \leq K_j \), where we consider \( K_j \) to be the integer part of the real number \( R_j \).

Expression (8) ensures that \( UE_{i,j} \) wins \( d_{i,j} \) or nothing and equation (9) ensures that the resource block \( k \) cannot be allocated to more than one user. Using the method in [6], termed virtual valuation, and in which the true revelation of the user valuation is the best strategy for him to maximize his own profit, we proceed as follows.

To determine the winners, MVNO_j maximizes the virtual valuation as follows

\[ \max_{i=1}^{N} \sum_{i=1}^{N} \phi_{i,j}(w_{i,j}) x_{i,j} \]  

s.t.

\[ \sum_{k=1}^{K_j} r_{i,j}^{k} = d_{i,j} x_{i,j} \]  

\[ \sum_{i=1}^{N} r_{i,j}^{k} \leq 1 \]  

(11)

where

\[ x_{i,j} = \begin{cases} 1 & \text{if } UE_{i,j} \text{ wins the auction} \\ 0 & \text{otherwise} \end{cases} \]

and

\[ \phi_{i,j}(w_{i,j}) = w_{i,j} - \frac{1 - F_{i,j}(w_{i,j})}{f_{i,j}(w_{i,j})} \]  

(13)

where

\[ f_{i,j} = \frac{\partial F_{i,j}(z)}{\partial z} \]  

(14)

According to the conventional Bayesian approach, we consider that the valuation \( v_{i,j} \) of the buyers is drawn from a distribution \( F_{i,j} \) known to the seller but not to the other bidders. We assume \( F_{i,j} \) to be monotone increasing and \( \frac{f_{i,j}}{1-F_{i,j}} \) to be monotone non decreasing, therefore the virtual valuation becomes monotone non decreasing [6].

We can define the virtual price \( p_{i,j}' \) as follows:

\[ p_{i,j}' = \max_{b_{-i,j}} \sum_{k \neq i}^{N} \phi_{k,j}(w_{k,j}) x_{k,j} - \max_{b_{-i,j}} \sum_{k \neq i}^{N} \phi_{k,j}(w_{k,j}) x_{k,j} \]  

(15)

The final allocation \( x_{i,j} \) is set to \( x_{i,j}' \) and the final price \( p_{i,j} \) is set to \( \phi_{i,j}(p_{i,j}) \).

It is interesting to note that the expected revenue \( P_E \) of any truthful mechanism under the Bayesian setting is equal to its
expected virtual surplus, \( \sum_j x_i \phi(w_{i,j}) \). Hence, the expected revenue \( P_E \) of Equation (2) becomes
\[
P_E = \sum_{i=1}^{N} p_{i,j} = \sum_{i=1}^{N} \phi_{i,j}(w_{i,j}) x'_{i,j}. \tag{16}
\]

2) Greedy algorithm approximation: To avoid the time complexity of the integer linear optimization in the winner and price determination problems, we propose hereafter a greedy algorithm to address this limitation by proposing a greedy algorithm that reduces the time complexity to a polynomial. At the higher-level, the weighted proportional fair allocation presents a linear time complexity.

Hence all the properties are satisfied in our auction algorithm.

V. EQUILIBRIUM ANALYSIS

In game theory, the solution of a game is characterized by Nash equilibria. According to [9], the set of bids of MVNO\(_1\)’s users \( b^* = (b^*_{1,j}, b^*_{2,j}, \ldots b^*_{N,j}) \) is a Nash Equilibrium if all users’ bids \( b_{i,j} \) are best response to the corresponding set \( b_{-i,j} \). Moreover \( b^*_{i,j} \), \( U_{E_{i,j}} \)'s bid, is considered as best response if \( U_{E_{i,j}} \), by knowing all other users’ bids, will not change his strategy; furthermore, even if user \( U_{E_{i,j}} \) gets to know other users bid strategies \( b_{-i,j} \), he will not change his bid strategy. We have to prove that:
\[
u_{i,j}(b^*_{i,j}, b_{-i,j}) \geq u_{i,j}(b_{i,j}, b_{-i,j}). \tag{17}\]

\( \forall \) possible \( b_{i,j} \). Based on that equilibrium in the auction\(_j\) game a second equilibrium should exist in auction\(_1\): there should exist \( S_j \) such that \( U_j(S_j, S^*_j) \geq U_j(S_j, S^*_j) \).

A. Nash Equilibrium for the lower-level auction

Based on the proof of Theorem 1 in [10], we can say that bidding the real valuation is a Nash equilibrium strategy, since with bidding other than \( b_{i,j} = v_{i,j} \), \( U_{E_{i,j}} \) will not maximize his utility, regardless of all the bids vector \( b_{i,j} \). So \( b^*_{i,j} = v_{i,j} \) is a Nash equilibrium point since it satisfies (17).

B. Nash equilibrium for the higher-level auction

In [11] the authors prove the Nash Equilibrium of the weighted proportional fair allocation we are using in the level2 auction. Nevertheless, in our model we have two games and proving the existence of the Nash equilibrium at this level of the auction requires proving that there exists a \( S^*_j \) such as
\[
U_j(S_j, S^*_j) \geq U_j(S_j, S^*_j) \tag{18}\]
where \( S_{-j} \) denotes the set of weights \( S \) excluding MVNO\(_j\) weight’s \( S_j \). According to [12], the auction\(_j\) game has an equilibrium point if \( U_j(S) \) depending on the set \( S \) of all MVNO’s strategies is continuous and concave in all \( S_j \in S \). Due to the fact that the expression of \( U_j \) is not in closed form, we will consider a numerical example, described hereafter, to simulate and evaluate the existence and uniqueness of the Nash equilibrium, showing that multiple Nash equilibria can indeed exist.

1) Scenario for the Nash Equilibrium evaluation: We consider a game where all the users \( U_{E_{i,j}} \) place bids in auction\(_j\) by revealing their true valuation independently from the \( N - 1 \) users bids, thus all \( b_{i,j} \in \{(b_{i,j}, b_{-i,j})\} \) satisfy (18). We suppose there are 2 virtual mobile operators (MVNO\(_1\) and MVNO\(_2\), each having \( N \) users competing in 2 auctions, respectively, auction\(_1\) and auction\(_2\). After collecting all the bids, MVNO\(_1\) and MVNO\(_2\) will place their bids \( B_1 = (S_1) \) and \( B_2 = (S_2) \) in order to obtain their part of the allocation.
(R₁ and R₂, respectively) and consequently pay $P₁ = S₁$ and $P₂ = S₂$. Our goal is to find the couple(s) $(S₁, S₂)$ satisfying \( \forall \) possible $S_j$:

\[
U₁(S₁, S₂) ≥ U₁(S₁, S_j)
\]

&

\[
U₂(S₁, S₂) ≥ U₂(S₁, S_j).
\]

In this perspective we simulate this scenario and evaluate the concavity of the utility function $U₁$ and $U₂$, and by that evaluate the existence and uniqueness of the Nash equilibrium point. Hence, we fix the cloud capacity $Q$, the number of users $N$, and by varying $S₁$ and $S₂$ in the interval $[0, S_{max}]$.

VI. SIMULATION RESULTS

In this section, we simulate the two-level auction using Matlab. Since the fundamental interest of a mobile operator is to maximize its revenue, we first evaluate the payoff of the MVNO and compare the performance achieved by the Integer Linear Program (ILP) and the greedy algorithm. Then, we analyze in a fine-grained way the MVNO’s payoff as a function of its bid and versus the total number of resource blocks with and without consideration of the virtual valuation. Finally, we simulate the Nash equilibrium scenario described in the previous section.

To achieve this, we consider a hierarchical model consisting of a Cloud-RAN, which is shared among 2 MVNOs, $MVNO₁$ and $MVNO₂$, both having $N$ subscribed users, where $N$ varies in the range $[20, 100]$. We consider the 3 following scenarios:

1) **Scenario 1**: The $N$ users are *homogeneous*; any given bidder $UE_{i,j}$ can ask for only 1 resource block such as $d_{i,j} = 1, \forall i \in I$ and $j \in \{1, 2\}$. The bid is $b_{i,j} = (d_{i,j}, w_{i,j})$, where the price $w_{i,j}$, offered to purchase $d_{i,j}$, is generated according to a uniform distribution in $[0, 1]$.

2) **Scenario 2**: The $N$ users are *heterogeneous*: 50% of the users ask for 1 resource block ($d_{i,j} = 1$) and the other 50% ask for 2 resource blocks ($d_{i,j} = 2$). The price $w_{i,j}$ is generated as in Scenario 1.

3) **Scenario 3**: Users are heterogeneous; their demands $d_{i,j}$ are generated according to a *uniform distribution* in $[1, 5]$.

The price $w_{i,j}$ is generated as in Scenario 1.

We set the Cloud capacity in terms of resource blocks to $Q = 20$, the bids of $MVNO₁$ and $MVNO₂$ to $S₁ = 4$ and $S₂ = 3$, respectively, and the reserved bid $S₀ = 0.5$. We assume that the valuation is generated from a uniform distribution.

To evaluate the effect of the *number of subscribed users* on MVNOs’ payoffs, we increase such parameter from 20 to 100. The results are shown in Figure 3. It can be observed that the 3 scenarios present similar performance when varying $N$. The payoff increases with $N$, attains a maximum value at $N = N_c$, and beyond this value the payoff remains constant. More specifically, the gap between the payoff value for small and medium number of users (i.e., $N = 20$ and $N = 30$), respectively, is high and then becomes low, and even null, for large values of $N$. Furthermore, we observe that the results given by the greedy algorithm are very similar to the optimal one.

In Figure 4 compares $MVNO₁$ and $MVNO₂$ payoffs by varying $MVNO₁$’s bid, $S₁$. We observe that $MVNO₂$’s payoff decreases with $S₁$; actually, for a given capacity $Q$ and $MVNO₂$’s bid, $S₂$, the allocation part $A₂$ will decrease when $S₁$ increases (we recall that $R_j = \frac{S_j}{S_j + S_{-j} + S₀}$). This trend is confirmed for the 3 considered scenarios. Conversely, $MVNO₁$’s payoff increases to attend a maximum and then decreases with $S₁$. We recall that the payoff function is $U₁ = P_E - P₁$, which depends linearly on $S₁$, since $P₁ = S₁$, and on $P_E$, which in turn is function of $R₁$, thus $S₁$. This explains the form of the curves. As observed before, also in this case, the greedy algorithm exhibits very good performance and provides results which are very close to the optimal solution.

Moreover, Figure 5 shows the revenue generated by $MVNO₁$ when varying the total number of resource blocks $Q$ auctioned between $MVNO₁$ and $MVNO₂$ in auction 1. The results show the reservation effect of the virtual valuation on the revenue: without considering the virtual valuation, the revenue decreases when $Q$ increases, while when using the virtual valuation the revenue remains constant when $Q$ increases. These results coincide with those already observed in [6].

Finally, we analyze the scenario described in subsection V-B1. We observe that the equilibrium uniqueness is not always guaranteed. A possible explanation for that is the lack of concavity of the utility function as mentioned in [12]. This problem can be overcome by requiring that the payoff functions of MVNOs and users satisfy concavity requirements under specific conditions on the variable space set.

VII. CONCLUSION

In this paper we proposed and evaluated an auction-based resource allocation mechanism in the context of Cloud-RAN. In such scenario, the spectrum is managed by several virtual mobile operators and the physical resource is owned by the C-RAN operator. Technically, our proposed approach consists of two coupled auctions in a hierarchical way: the lower-level auction between end users and the virtual operators, and the higher-level one between MVNOs and the C-RAN operator. We showed that our proposed auction-based approach satisfies fundamental economic properties, including truthfulness. We evaluated in typical network scenarios the validity of the proposed approach, showing that we are able to allocate resources efficiently, which is a key feature for next generation, 5G mobile networks. We plan to extend our work by enhancing the mechanism so that the solution converges to a unique and efficient Nash equilibrium point.
